In the present work it is suggested that the degree of fibre–matrix bonding can be quantified by means of an energy for the nucleation of an interfacial debond, rather than by using a stress-based interfacial parameter. The energy necessary to initiate/nucleate an interfacial crack from its associated transverse fibre break during a single-fibre fragmentation test is calculated. The interface energy for the initiation of debonding is shown to be a function of the fibre and matrix geometrical and material characteristics, and of the initial debonding length. The novelty of the present work lies in the in-depth examination of the relative roles of the physical parameters that appear in the proposed theoretical model.

(Keywords: fragmentation test; interfacial debonding; energy balance model)

INTRODUCTION

The adhesion between a rigid fibre and a more ductile polymer matrix is usually measured by micromechanical testing using single-fibre microcomposite specimens. The single-fibre composite (or fragmentation) test is one of the most studied[1–5]. It involves a rather complex interfacial stress state, but only simplistic force equilibrium, and shear-lag or elastic–plastic analyses are used to analyse the test results in terms of the stress transfer ability, a mechanical parameter usually loosely termed the interfacial shear strength (τ). Despite the popularity of this experimental approach and the large amount of experimental results obtained over the years, some investigators[6–9] have suggested that τ may not be the critical factor governing fibre–matrix debonding, and that in the search for fracture criteria an energy-based theory is usually a better approach than a theory based on the identification of a stress at a point. We reached the same conclusion following an experimental study of the effects of water and temperature on glass/epoxy composites[9]. In that study, it was found to be impossible to interpret the results of fragmentation tests using the classical stress-based Kelly–Tyson approach, mostly because of the presence of extensive interfacial debonding (for example, following 2 h immersion at 95°C) and of the lack of a saturation state (usually after long immersion times, or under high temperatures). A theoretical model and first direct experimental results were recently presented by Wagner *et al.*[10]. The concept proposed is an energy balance scheme for the analysis of the initial interfacial debonding that arises as fibres progressively begin to break during the fragmentation test. This approach makes use of measurements performed at low strain levels, enabling the determination of the interfacial fracture energy associated with the initial debond, even in the case of composites that would never reach saturation during a fragmentation test. Moreover, such approach has the advantage of incorporating the length of the nucleating debond zone as a parameter, in contrast with the classical force balance interpretation of the fragmentation test for which the presence of such interfacial debonding zone is a complicating factor. However, as the energy balance presented here compares energies before and after fracture of the fibre and the interface, rather than computing energy changes as the interfacial debond propagates, it is not a strict fracture mechanics analysis.

In the present article, we present a novel in-depth study of the relative roles of the physical parameters that
