KINETICS OF DENSIFICATION BY SOLUTION-REPRECIPITATION

A. MORTENSEN[†]

(Received 19 April 1996)

Abstract—The densification rate and microstructural evolution of powder compacts densifying by solution-reprecipitation in the presence of a liquid phase are predicted with the assumption that solid particles are equisized spheres randomly packed and pulled together by a liquid that wets perfectly both the solid and its grain boundaries. The influences of applied pressure, initial packing density, and of the "sphering force" due to changes in solid particle shape are accounted for. The resulting sintering rate retains approximately the one-third power law dependence of linear shrinkage on time predicted by Kingery, and shows good agreement with published experimental data. The analysis is extended to include the role of particle coarsening, so as to assess its importance and influence in densification kinetics. *Copyright © 1997 Acta Metallurgica Inc.*

1. INTRODUCTION

Liquid phase sintering is one of the most industrially significant powder densification processes. In its usual form, this process consists of heating, sometimes under pressure, a mixed powder compact until a small amount of chemically stable liquid phase forms and greatly accelerates sintering of the powders. Because of its practical importance, a large body of research, summarized in two monographs [1, 2], has been conducted on liquid phase sintering, towards identification and quantification of the rate of sintering, and towards prediction of the resulting material microstructure.

There is broad agreement that, despite considerable microstructural complexity and system-to-system specificities, the densification of liquid phase sintered structures proceeds essentially in three stages. The first of these is a relatively rapid rearrangement of solid particles, which begins immediately upon formation of the liquid. The second stage, solution-reprecipitation, is observed only in systems featuring some solubility of the remaining solid phase in the liquid phase. In the third stage, microstructural coarsening is observed in many systems, accompanied by much slower solid-state sintering in systems where there is formation of a network of solid bridges between touching solid particles.

The first stage, rearrangement, is geometrically complex. When the liquid phase forms, the remaining solid phase particles change position under the action of capillary forces, to eliminate void spaces within the structure. Rearrangement is complicated by several capillary and dissolution phenomena; however, in the simpler systems, the observed densification kinetics are predominantly limited by viscous flow of the liquid. Hence, as first shown by Kingery [3], the rate of densification during rearrangement is roughly constant, and inversely proportional to the solid particle radius if monosized solid phase powders are used. Rearrangement stops either when the liquid fills all pore space present, or when the solid particles are packed to the maximum volumetric density that can be attained from the initial mixed powder structure without deformation of the solid particles.

When rearrangement does not fully densify the compact, solution-reprecipitation can provide a rapid alternate densification path in systems where there is some solubility of the solid in the liquid phase. Solution-reprecipitation is the process whereby solid phase material along contact areas between touching solid particles dissolves into the liquid, and deposits elsewhere along the liquid/solid interface. The net result of this process is that solid particles are deformed, in a manner that causes an increase in their packing density and, hence, a reduction in pore volume within the powder compact. Resulting microstructures feature, in non-faceted solid/liquid systems, flattened spheres typical of the "grain shape accommodation" that is observed, for example, in heavy alloy microstructures (examples are given on pages 7 and 104 of the monograph by German [2]).

Despite considerable research on the kinetics of densification during this second, solution-reprecipitation, phase of liquid phase sintering, few quantitative models exist. Essentially, the only quantitative prediction of the rate of densification
